Coarticulatory effects on lingual articulations in the production of Cantonese syllable-final oral stops
Jonathan Yip

Introduction
Previous studies have determined that the inaudibly-released syllable-final oral stops [p’ t’ k’] of Cantonese are primarily cued by spectral formant transitions into stop closure during the preceding vowel (Ciocca et al., 1994; Khouw & Ciocca, 2006). However, younger speakers are reported to have a tendency to either merge the alveolar and velar codas [t’] and [k’] or produce a full glottal closure in lieu of or immediately preceding the coda gesture (Zee, 1999; Law et al., 2001), potentially leading to perceptual confusions between alveolar and velar stop place. While prior perceptual work has attributed this phenomenon to the phonological loss of a coronal-dorsal coda place contrast in younger speakers, articulatory investigations of the loss of [t’]–[k’] contrasts for this segment of the population are lacking. The goal of this study is to understand whether young-adult speakers consistently produce lingual gestures that correspond to the coda stops [t’] and [k’] and whether there are strong anticipatory coarticulatory influences that could mask the acoustic cues to coda place according to the place of the following consonantal gesture.

Methodology
In this study, ultrasonic tongue imaging was used to examine the lingual dynamics during the production of coda stops [t’, k’] in 24 Cantonese disyllabic words. These target words were selected such that the initial syllables containing the coda stops were one of 4 morphemes (發 [fat’], 法 [fat’], 白 [pak’], and 揭 [p4ak’]) and the second syllables contained onset consonants with labial, coronal, and dorsal place of articulation, e.g. [fat’ m3æn] vs. [fat’ tæt] vs. [fat’ k3ok] and [pak’ p3æm2] vs. [pak’ τ2u2] vs. [pak’ k3ep2]. Ultrasonic images of the productions of 5 native speakers of the Hong Kong variety of Cantonese were collected using a Telemed ClarUs machine at a frame rate of 60 fps and sequences of ultrasonic frames were extracted during the interval [...V1C1C2V2...] within each target item, as determined from the synchronized acoustic signal. Splines corresponding to lingual contours in each frame within the intervals of interest were traced and extracted in EdgeTrak (Li et al., 2005), as well as contours of the palate. To assess the achievement of syllable-final stop gestures, minimum values of distance between the tongue contour and coronal and dorsal regions of the palate (“aperture”) during C1–C2 closure were calculated at each frame time. For each talker, minimum aperture distances corresponding to the coda gesture were compared in a linear mixed-effects model with fixed effects of articulator (tongue tip, tongue dorsum) and place context (labial, coronal, dorsal) and the random effect of item.

Results & Discussion
The data reveal that the 5 speakers’ productions fell into three general categories of articulatory patterns: gestural preservation (S5), gestural reduction or partial loss (S1 and S2), and near-complete loss (S3 and S4). In the preservation pattern, lingual articulations consistently achieved full stop closures near the end of the first vowel, regardless of articulator and place context. In the reduction/partial loss pattern, lingual articulations were greatly reduced in labial contexts but involved strong effects of tongue-tip to tongue-dorsum coproduction in lingual-lingual sequences (t+DORSAL and k+CORONAL). For talkers exhibiting nearly complete loss of the syllable-final stop articulations, movements of the tongue during the C1–C2 closure interval corresponded strongly to the place of the following onset consonant only, with little evidence of lingual coproduction behaviors. Differences in speech rate are also observed and could be the source of gestural timing variation between speakers. The articulation of Cantonese syllable-final stops were varied — not only between
talkers but also before syllables differing in onset place—and this variability even occurred within the same morpheme (Chinese character) in different contexts. The results of this study provide a richer picture as to whether and how the inaudibly-released, syllable-final, lingual oral stops in Cantonese are produced by young-adult talkers.
